

What are tissue engineering and regenerative medicine?

Tissue engineering evolved from the field of biomaterials development and refers to combining scaffolds, cells, and biologically active molecules into functional tissues. The goal of tissue engineering is to assemble such fully functional constructs that restore, maintain, or improve damaged tissue or a whole organ. Skin and cartilage are examples of engineered tissue that have already been approved by the FDA; however, currently they have limited use in human patients.

Regenerative medicine is a broad field that includes tissue engineering but also incorporates the idea of self-healing – where the body uses its own systems, sometimes with help from added biological material from outside the body, to recreate cells or rebuild organs. The terms “tissue engineering” and “regenerative medicine” have become largely interchangeable, as the field hopes to focus on cure instead of treatment for complex, often chronic diseases.

The field continues to evolve. In addition to medical applications, non-therapeutic applications include using tissues as biosensors to detect biological or chemical threat agents, and tissue chips that can be used to test the toxicity of an experimental medication.

How do tissue engineering and regenerative medicine work?

Source: Northwestern University

Cells are the building blocks of tissue, but tissues are the basic unit of function in the body. Generally, groups of cells make and secrete their own support structures, called the extra-cellular matrix. This matrix, or scaffold, does more than just support the cells; it also acts as a relay station for various signaling molecules. Thus, cells receive messages from many sources that become available from the local environment. Each signal can start a chain of responses that determine what happens to the cell. By understanding how individual cells respond to signals, interact with their environment, and organize into tissues and organisms, researchers have been able to manipulate these processes to mend damaged tissues or even create new ones.

The process often begins with building a scaffold from a wide set of possible sources, from proteins to plastics. Once scaffolds are created, cells with or without a “cocktail” of growth factors can be introduced. If the environment is fertile, a tissue develops. In some cases, the cells, scaffolds, and growth factors are all mixed together at once, allowing the tissue to “self-assemble.”

Another method to create new tissue uses an existing scaffold. The cells of a donor organ are stripped and the remaining collagen scaffold is used to grow new tissue. This process has been used to bioengineer heart, liver, lung, and kidney tissue. This approach holds great promise for using scaffolding from human tissue discarded during surgery, combined with a patient’s own cells to make customized organs that would not be rejected by the immune system.

How do tissue engineering and regenerative medicine fit in with current medical practices?

Source: Stephen Badylak, University of Pittsburgh

Currently, tissue engineering plays a relatively small role in patient treatment. Supplemental bladders, small arteries, skin grafts, cartilage, and even a full trachea have been implanted in patients, but the procedures are still experimental and very costly. While more complex organ tissues like heart, lung, and liver tissue have been successfully recreated in the lab, they are a long way from being fully reproducible and ready to implant into a patient. These tissues, however, can be quite useful in research, especially in drug development. Using functioning human tissue to help screen medication candidates could speed up development, saving money and animals, and provide key tools for facilitating personalized medicine.

What are NIBIB-funded researchers developing in the areas of tissue engineering and regenerative medicine?

Research supported by NIBIB includes development of new scaffold materials and new tools to fabricate, image, monitor, and preserve engineered tissues. Some examples of research in this area are described below.

- **Controlling stem cells through their environment:**

For many years, scientists have searched for ways to control how stem cells develop into other cell types, in the hopes of creating new therapies. Two NIBIB researchers have grown pluripotent cells—stem cells that have the ability to turn into any kind of cell—in different types of defined spaces and found that this confinement triggered very specific gene networks that determined the ultimate fate for the cells. Most other medical research on pluripotent stem cells has focused on modifying the combination of growth solutions in which the cells are placed. The discovery that there is a biomechanical element to controlling how stem cells transform into other cell types is an important piece of the puzzle as scientists try to harness stem cells for medical uses.

- **Implanting human livers in mice:**

NIBIB-funded researchers have engineered human liver tissue that can be implanted in a mouse. The mouse retains its own liver as well, and therefore its normal function; but the added engineered human liver can metabolize drugs in the same way humans do. This allows researchers to test susceptibility to toxicity and to demonstrate species-specific responses that typically do not show up until clinical trials. Using engineered human tissue in this way could cut down on the time and cost of producing new drugs, as well as allowing critical examinations of drug-drug interactions within a human-like system.

- **New hope for the bum knee:**

An NIBIB-funded tissue engineer has developed a biological gel that can be injected into a cartilage defect following microfracture surgery to create an environment that facilitates regeneration. However, in order for this gel to stay in place within the knee, researchers also developed a new biological adhesive that is able to bond to both the gel as well as the damaged cartilage in the knee, keeping the newly regrown cartilage in place. The gel/adhesive combo was successful in regenerating cartilage tissue following surgery in a recent clinical trial of fifteen patients, all of whom reported decreased pain at six months post-surgery. In contrast, the majority of microfracture patients, after an initial decrease in pain, returned to their original pain level within six months. This researcher worked in collaboration with another NIBIB grantee to image the patients who had undergone surgery enabling scientists to combine new, non-invasive methods to see the evolving results in real-time.

- **Engineering mature bone stem cells:**

Researchers funded by NIBIB completed the first published study that has been able to take stem cells all the way from their pluripotent - state to mature bone grafts that could potentially be transplanted in a patient. Previously, investigators could only differentiate the cells to a primitive version of the tissue which was not fully functional. Additionally, the study found that when the bone was implanted in immunodeficient mice there were no abnormal growth afterwards—a problem that often occurs after implanting stem cells or bone scaffolds alone.
